7   Language Input to Blind Infants/Toddlers

Introduction

9   The early language skills of blind children are highly variable (**campbell_inprep?**),

10   with some blind children demonstrating age-appropriate vocabulary from the earliest stages

11   of language learning (Bigelow, 1987; Landau & Gleitman, 1985), while others experience

12   large and persistent language delays (**CITE?**). Canonically, blind adults become competent

13   speakers of their language and are even reported to have faster language processing skills

14   than their sighted peers (Röder, Demuth, Streb, & Rösler, 2003; Röder, Rösler, & Neville,

15   2000). The causes of this variability and the later ability to "catch up" remain poorly

16   understood. In particular, the higher incidence of severe language delays in blind children

17   yields questions about the process of language development in the absence of visual

18   perception: what makes the language learning problem different and apparently more

19   difficult for the blind child? There are multiple possible contributors, including

20   characteristics of the child (e.g., visual acuity, comorbid conditions, gender) as well as

21   characteristics of the environment (e.g., access to early intervention services; school setting;

22   caretakers tailoring interactions to their child's sensory access). Here, we explore the

23   characteristics of the language environment of blind children as it compares to the language

24   environment of their sighted peers. In doing so, we begin to narrow down the role that visual

25   input plays in language development, among all other factors.

26   Among both typically-developing children and children with developmental differences,

27   language input can predict variability in language outcomes (Anderson, Graham, Prime,

28   Jenkins, & Madigan, 2021, 2021; Gilkerson et al., 2018; Huttenlocher, Haight, Bryk, Seltzer,

29   & Lyons, 1991; Huttenlocher, Waterfall, Vasilyeva, Vevea, & Hedges, 2010; Rowe, 2008,

30   2012). There are many ways to operationalize language input, that tend to be grouped into

31   **quantity of language input** and **input characteristics** (often discussed as **quality of**

32   **language input**, c.f. MacLeod and Demers (2023)). Quantity of language input can be

33 broadly construed as the number of words or utterances a child is exposed to. At a coarse

34 level, children who are exposed to more speech (or sign, **watkins_deaf_1998?**) tend to

35 have better language outcomes (Anderson et al., 2021; Gilkerson et al., 2018; Huttenlocher et

36 al., 1991; Rowe, 2008). However, if only the *amount* of language exposure mattered, then

37 infants should be able to sit in front of the television all day and become fluent language

38 users. Yet young children struggle to learn language from video alone (e.g., Roseberry,

39 Hirsh-Pasek, & Golinkoff, 2014 May-Jun).

40 The specific characteristics of that language input are perhaps even more important

41 (Hirsh-Pasek et al., 2015; Rowe, 2012), although it is somewhat trickier to turn the

42 qualitative characteristics of language input into operationalizable properties. In this

43 analysis, we move away from describing these linguistic characteristics as "quality"

44 measures[^1]. Rowe and Snow (Rowe & Snow, 2020) divide this space into three dimensions

45 of language input: interactive features (e.g., parent responsiveness, speech directed *to* child

46 vs. overheard; conversational turn-taking), linguistic features (e.g., lexical diversity,

47 grammatical complexity), and conceptual features (e.g., topic diversity). These

48 environmental features at various stages interact with the child's own cognitive, linguistic,

49 and conceptual abilities.

50 [^1] In the field thus far, the directionality of the term "quality" has favored the types

51 of language used by white and abled groups as immutable universal standards, thereby

52 framing racialized and disabled peoples' language as deficit and "low quality" by nature.

53 Describing a singular source of input variation as "high quality" ignores the sociocultural

54 variation of talk styles, and the presence of many rich sources of information that children

55 can learn from (MacLeod & Demers, 2023).

56 An important social feature of the language environment is the amount of interactivity

57 in parent-child communication. Prior literature reports that back-and-forth communicative

58 exchanges (also known as conversational turns) between caregivers and children predict

59 better language learning across infancy (Donnellan, Bannard, McGillion, Slocombe, &

60 Matthews, 2020; Goldstein & Schwade, 2008) and toddlerhood (Hirsh-Pasek et al., 2015;

61 Romeo et al., 2018), indicating that parents' active response to their children's actions and

62 utterances supports their learning. Adults' attunement to children's non-linguistic cues of

63 attention and interest, like pointing or eye gaze, also contributes to interactivity. In infancy,

64 words heard in contexts where the adult and child share joint attention are more likely to be

65 learned (Tomasello & Farrar, 1986; **lucca2017?**). Parents' interaction with their child and

66 the world around them ties together the linguistic and conceptual characteristics of the

67 language input, to which we turn next.

68   Two commonly-analyzed linguistic features are lexical diversity (often measured as

69 type/token ratio) and syntactic complexity. In accounts of the development of sighted

70 children, lexical diversity of language input seems to exert different effects as children get

71 older. In early infancy, children who are exposed to more repetitions (and therefore less

72 lexical diversity) at 7 months have higher vocabulary at age 2 (Newman, Rowe, & Bernstein

73 Ratner, 2016). This relationship later flips: toddlers who are exposed to greater diversity of

74 words in their language input tend to have larger vocabulary scores (Anderson et al., 2021;

75 Hsu, Hadley, & Rispoli, 2017; Huttenlocher et al., 2010; Rowe, 2012; Weizman & Snow,

76 2001). Lexical diversity is intertwined with input quantity: parents who talk more also tend

77 to provide more lexical diversity (Hoff & Naigles, 2002 Mar-Apr). Likewise, the diversity of

78 syntactic constructions in parental language input is associated both with children's

79 vocabulary growth and structure diversity in their own productions (De Villiers, 1985;

80 Hadley et al., 2017; Hoff, 2003 Sep-Oct; Huttenlocher, Vasilyeva, Cymerman, & Levine, 2002;

81 Huttenlocher et al., 2010; Naigles & Hoff-Ginsberg, 1998).

82   The conceptual dimension of language input aims to capture the extent to which the

83 language signal maps onto objects and events in the world, which may be a noisy and

84 somewhat opaque connection even with visual input [CITE]. As with the other dimensions,

the pieces of the conceptual content of language input that are most informative may shift across developmental time: as children develop, their ability to represent abstract, displaced, decontextualized referents improves [CITE]. For example, young infants are more likely to learn a new word when the referent is perceptually salient, dominating their field of view (Yu & Smith, 2012). Parents responding to a child's point and labeling the object of interest might boost learning in that instance (Lucca & Wilbourn, 2018). By contrast, *displaced* language use– that is, talking about past, future, or hypothetical events, or people and items that are not currently present in the environment– may be beneficial at later stages of development (**rowe_decontextualized_2013?**). Indeed, greater decontextualized language use in speech to toddlers predicts kindergarten vocabulary (Rowe, 2012), children's own decontextualized language use (Demir, Rowe, Heller, Goldin-Meadow, & Levine, 2015), and academic achievement in adolescence (Uccelli, Demir-Lira, Rowe, Levine, & Goldin-Meadow, 2019). Decontextualized language may support language learning because it provides an opportunity to discuss a broader range of topics and reflects typical adult language usage, which is often abstract (**CITE?**). It also provides the opportunity for more lexical and syntactic diversity.

From this review, it appears that sighted children learn about the world and language simultaneously from many sources, including sensory perception, linguistic input, and conceptual and social knowledge. For blind children, however, language input may constitute a greater proportion of the available clues for learning than for sighted children; in the absence of visual input, language is an important source of information about the world (E. E. Campbell & Bergelson, 2022). Syntactic structure provides cues to word meaning that may be lost without visual cues, such as the relationship between two entities that aren't within reach (**gleitman1990?**). In our review so far, we have presented a pattern wherein the features of the input that are most helpful for language learning change over the course of children's development: early on, many of these cues require visual access,such as parental gaze, shared visual attention, pointing to remote object and the presence of salient objects in

the visual field. Only later in development do the handholds to language learning become more abstract. This may be part of the reason why language delays are common in blind toddlers, but often resolved in older childhood [CITE]. If direct sensory access is the key to unlocking the meaning of early words, it may take longer to gain enough environmental experience to make early language learning strides– that is, it may take longer in infancy to build a "semantic seed" (**babineau2021?**; **babineau2022?**). By hypothesis, once this initial seed of linguistic knowledge is acquired, blind children and sighted children alike are able to use more abstract and linguistic features as cues, and learning proceeds rapidly (E. E. Campbell & Bergelson, 2022). Nevertheless, we cannot assume that access to visual experience is the *only* difference in the language learning experiences for blind and sighted children. The language input itself may very well differ for blind children relative to sighted children, for a variety of reasons.

First, speakers regularly tailor input to communicate efficiently with the listener (**grice1975?**). Parents are sensitive to their child's developmental level and tune language input accordingly (Snow, 1972; Vygotsky & Cole, 1978). Child-directed speech is one example–whereby parents speak to young children with exaggerated prosody, slower speech rate, and increased vowel clarity (Bernstein Ratner, 1984; Fernald, 1989), which is in some cases helpful to the young language learner (Thiessen, Hill, & Saffran, 2005). Parents show increased alignment (a tendency to re-use the conversation partner's expressions) for younger children, which decreases as children get older (Yurovsky, Doyle, & Frank, 2016). When interacting with infants and toddlers, parents repeat words more often than when interacting with older children or adults (Snow, 1972). Communicative tailoring is also common in language input to children with disabilities, who tend to receive simplified, more directive language input, and less interactive input compared to typically-developing children (Yoshinaga-Itano, Sedey, Mason, Wiggin, & Chung, 2020; **dirks2019?**).

In addition to tailoring communication to children's developmental level, speakers also

adjust their conversation in accordance with the conversation partner's sensory access (Gergle, Kraut, & Fussell, 2004; Grigoroglou, Edu, & Papafragou, 2016). In a noisy environment, speakers will adapt the acoustic-phonetic features of their speech with the intent to make it easier for their interlocutor to understand them (**hazan_acoustic-phonetic_2011?**), which demonstrates sensitivity to even temporary sensory conditions of their conversation partner. When describing scenes, speakers aim to provide the information their listeners lack but avoid redundant visual description (Ostarek, Paridon, & Montero-Melis, 2019; **grice1975?**). During in-lab tasks with sighted participants, participants tailor their descriptions and requests by verbally providing visually-absent cues when an object is occluded to their partner (Hawkins, Gweon, & Goodman, 2021; Rubio-Fernandez, 2019; **jaraettinger2021?**). These results suggest that adults and even infants (Chiesa, Galati, & Schmidt, 2015; Ganea et al., 2018; Senju et al., 2013) can flexibly adapt communication to the visual and auditory abilities of their partner.

Curiously though, these patterns are not borne out in the existing literature on interactions between blind infants and their sighted parents. We might expect parents to verbally compensate for missing visual input, resulting in parents providing more description of the child's environment. Instead, caregivers of blind children seem to restrict conversation to things that the blind child is currently engaged with, rather than attempt to redirect their attention to other stimuli (Andersen, Dunlea, & Kekelis, 1993; J. Campbell, 2003; Kekelis & Andersen, 1984). In naturalistic settings, parents of blind children use *fewer* declaratives and *more* imperatives than parents of sighted children, suggesting that children might be receiving less description than sighted children (Kekelis & Andersen, 1984; Landau & Gleitman, 1985). On the other hand, some parents may adapt to their children's visual abilities in specific contexts. Tadić, Pring, and Dale (2013 Nov-Dec) and colleagues find that in a structured book reading task, parents of blind children provide more descriptive utterances than parents of sighted children. Further, parents of blind children provide more tactile cues to initiate interactions or establish joint attention (Gunilla M. Preisler, 1991;

165 Urwin, 1983), which may serve the same social role as shared gaze in sighted children. These

166 mixed results suggest that parents of blind children might alter language input in some

167 domains but not others.

168   Better understanding how sensory perception and linguistic input interact to influence

169 blind children's language outcomes is of great clinical and scientific importance. Based on

170 our own interactions with participants' families in the present study, parents are looking for

171 evidence-based guidance to help them support their children's language development. If

172 properties of language input influence the likelihood of language delays among blind infants

173 and toddlers (**campbell_inprep?**), capturing this variation may reveal a more nuanced

174 picture of how infants use the input to learn language. By contrast, if there is no

175 relationship between language input properties and children's language outcomes, then

176 trying to modify language input can be one less worry for caregivers. In the present study,

177 we examine daylong recordings of the naturalistic language environments of blind and

178 sighted children in order to characterize the input to each group. We first measure input

179 quantity (adult word count) and analyze several characteristics that may be information-rich

180 learning cues, including interactivity(conversational turn counts, proportion of child-directed

181 speech), conceptual features (temporal displacement, sensory modality), and linguistic

182 complexity (type/token ratio and mean length of utterance). We then link these properties

183 of language input to language outcomes and explore whether the effects vary as a function of

184 children's perceptual ability.

Methods

Participants

187   29 blind infants and their families participated in this study. Blind participants were

188 recruited through opthamologist referral, preschools, early intervention programs, social

189 media, and word of mouth. To be eligible for this study, participants had to be 6–30 months

190 old, have no additional disabilities (developmental delays; intellectual disabilities, or hearing

loss), and be exposed to $\geq$ 75% English at home. Given the wide age range of the study, to control for age, each blind participant was matched to a sighted partcipicant, based on age ($\pm$ 6 weeks), gender, maternal education ($\pm$ one education level: less than high school diploma, high school diploma, some college / Associate's, Bachelor's, graduate school), and number of siblings ($\pm$ 1 sibling). When more than one match was available, we prioritized matching the blind participants as closely as possible on each characteristic in the preceding order. Caregivers were asked to complete a demographics survey and the MacArthur-Bates Communicative Development Inventory (CDI, Fenson et al., 1994) within one week of the home language recording. See Table @ref(tab: participant-characteristics) for sample characteristics.

% latex table generated in R 4.0.2 by xtable 1.8-4 package % Fri Apr 21 15:45:26 2023

Recording Procedure

Eligible families were asked to complete two surveys and complete a daylong home language recording. For the recording portion of the study, caregivers of participating infants received a LENA wearable audio recorder (Ganek & Eriks-Brophy, 2016) and vest. They were instructed to place the recorder in the vest on the day of their scheduled recording and put the vest on their child from the time they woke up until the recorder automatically shut off after 16 hours (setting vest nearby during bath, nap, and car times). They were also instructed how to pause the recording at any time, but asked to keep these pauses to a minimum. Actual recording length ranged from 8 hours 17 minutes to 15 hours 59 minutes (15 hours 16 minutes).

Processing

Audio recordings were first processed by LENA proprietary software, creating algorithmic measures such as conversational turn counts. Each recording was then run through an in-house automated sampler that selected 15- non-overlapping 5-minute

segments, randomly distributed across the duration of the recording. The process output a codeable ELAN file (.eaf, (**ELAN?**)). Each segment consists of 2 core minutes of annotated time, with 2 minutes of listenable context marked out preceding the annotation clip and 1 minute of additional context following the annotation clip. Each file therefore contains 30 minutes of coded recording time and 75 minutes of total time listened. Because these segments were sampled randomly, and not on a high-volubility measure such as conversational turns or adult speech density, the amount of time with codeable speech input varied for each recording. Indeed, across participants roughly 27% of the 2-minute coding segments contained no speech at all.

Once the randomly selected segments were annotated, we also chose to annotate 15 additional segments specifically for their high levels of speech. To select these segments of dense talk, we first conducted an automated analysis of the audio file using the voice type classifier for child-centered daylong recordings (**lavechin2020?**) which identified all human speech in the recording. The entire recording was then broken into 2-minute chunks marked out at zero-second timestamps (e.g. 00:02:00.000 to 00:04:00.000). Each of these chunks was then ranked highest to lowest by the total duration of speech contained within the boundaries. For our high volubility sample, we chose the highest-ranked 15 segments of each recording, excluding those that overlapped with already-coded random segments.

Annotation

Trained annotators listened through each 2-minute segment plus its surrounding context and coded it using the Analyzing Child Language Experiences around the World (ACLEW) Daylong Audio Recording of Children's Linguistic Environments (DARCLE) annotation scheme (Soderstrom et al., 2021). Prior to annotating lab data, annotators are trained on previously coded samples of child recordings and are required to reach 95% overall agreement with the gold standard version of the file for three different age ranges: 0-7 months, 8-18 months, and 19-36 months. For more information about this annotation

scheme and the larger project, please see the ACLEW homepage

(https://sites.google.com/view/aclewdid/home). Following the first pass, all files were by a

highly-trained "superchecker" to ensure the consistency of annotations.

This annotation scheme is designed to capture both utterances by the target child and speech in the child's environment, including adults, other children, and pre-recorded electronic speech (e.g. toys, television, the radio). Annotators segment the duration of each utterance on a separate coding tier for each unique speaker (exceptions: all electronic speech is coded on the same tier, and some speakers who appear briefly in these files were not easily distinguishable from others by annotators naive to their identities, so they may be concatenated on the same tier). Speech by people other than the target child is transcribed using an adapted version of CHAT transcription style (MacWhinney, 2019), dubbed minCHAT for the ACLEW project (Soderstrom et al., 2021). Because the majority of target children in the project are pre-lexical or phonetically immature, utterances produced by the target child are not transcribed.

Each utterance is coded for additional linguistic properties from a set of pre-determined categories. Target child utterances are coded for vocal maturity, lexical status, and multi-word status. Vocal maturity classifies utterances into the following categories: laughing; crying; canonical syllables that contain a consonant-like and vowel-like sound component, including both babbling and identifiable words; non-canonical syllables, which do not contain both consonant and vowel portions, or which do not transition between them in a speech-like way; and unsure, when the vocalization type is unclear. Each vocalization that contains canonical syllables is then coded for lexical status (does it contain an identifiable lexical item?). Finally, each utterance with a lexical item is coded for multi-word status (does it contain more than one unique word type?).

Environmental speech from everyone else is coded for the addressee of each utterance: speech directed to a child, whether or not it is directed to the target child; adult-directed

268 speech; speech directed to both an adult and a child; speech directed to pets or other animals;

269 speech with an unclear addressee; or speech directed towards a recipient that doesn't fit into

270 another category (e.g. voice control of Siri or Alexa, prayer to a metaphysical entity).

<center>Results</center>

Measuring Properties of Language Input

273 We first seek to assess whether language input to blind children is categorically

274 different from the language input to sighted children, along the dimensions of quantity,

275 interactiveness, linguistic properties, and conceptual properties. For continuous variables, we

276 test for group differences using xxx, and for categorical variables we test for differences with

277 xxx.,We use non-parametric versions of these tests when a Shapiro-Wilks test indicates that

278 the variable is not normally distributed. Because this analysis involves multiple tests of the

279 null hypothesis (*that there is no difference in the language input to blind vs. sighted kids*), we

280 use the conservative Bonferroni correction to set our threshold for significance ($p = 0.05$ / 8

281 tests = 0.01).

282 **Language Input Quantity.**   We first compare the quantity of language input to

283 blind and sighted children using two measures of the number of words in their environment:

284 LENA's automated Adult Word Count and word token count from our manual annotations.

285 Shapiro-Wilks tests indicated that both of these variables were normally distributed (ps >

286 .05).

287 Turning first to LENA's automated measure, a two-sample t-test shows that despite

288 wide variability in the number of words children hear (Range: 6233–31745 words$_{\text{blind}}$,

289 6027–25500 words$_{\text{sighted}}$), blind and sighted children do not differ in language input quantity

290 ($t(45.26) = $ -1.99, $p = $ .053). If we instead measure this using word counts from the

291 transcriptions of the audio recordings, we find parallel results: blind and sighted children do

292 not differ in language input quantity ($t(27.00) = 0.08$, $p = $ .939); see Figure 1.
Figure 1. Comparing LENA-generated adult word counts (left) and transcription-based word counts in the input of blind and sighted children. Each dot represents the estimated number of words in one child's recording.

Interactiveness. We compared the proportions of child-directed speech (CDS) between the blind children and their sighted matches. Each proportion was calculated as the number of utterances produced by someone *other* than the target child (non-CHI utterances) tagged with a child addressee out of the total number of non-CHI utterances for each sensory group. A two-sample test for equality of proportions revealed no significant difference in the overall proportions of CDS to blind children and CDS to sighted children.

We next compare the number of conversational turn counts for blind and sighted children, using LENA's automated Conversational Turn Count measure. This measure is not normally distributed ($W = 0.92$, $p = .924$). Despite wide variability in conversational turns (210–1436 $_{blind}$, 112–1348 $_{sighted}$), we find no evidence for group-level differences between blind and sighted children ($W = 456$, $p = .585$).
Figure 2. Comparing LENA-generated conversational turn counts (left) and proportion of utterances in child-directed speech (center). Each dot represents one child's recording. The full breakdown by addressee is shown in the rightmost panel.

Linguistic Features.

306   For linguistic features, we first measure the proportion of unique words divided by the

307   number of total words in the input, or type-token ratio, from the manual annotations.

308   Because this variable met the normality assumption, we performed a two-sample t-test.

309   Results indicated that there was no significant difference in the type-token ratio between the

310   two groups ($t(26.75)$ = -1.29, p = .208). This suggests that, on average, the type-token ratio

311   is similar for blind (M: 0.35) and sighted (M: 0.32) children (see Figure **??**). These results

312   provide evidence that the variety of words in the input is not affected by children's vision.

313   We also analyzed the syntactic complexity of children's language input, approximated

314   as utterance length in morphemes. Each utterance by a non-CHI speaker was tokenized into

315   morphemes using the 'morphemepiece' R package [CITE]. We then calculated the mean

316   length of utternace (MLU) per speaker in each audio recording, and then compared the

317   MLU of environmental speech to blind children (M(SD) = 5.08 (1.29)) to that of sighted

318   children (M(SD) = (M(SD) = 4.47 (1.39)); this variable was normally distributed (W = 0.92,

319   p = .924). A two-sample t-test revealed that the MLU was slightly but significantly higher in

320   speech to blind children than to their sighted peers ($t(147.71)$ = -2.80, p = .006).

321   **Conceptual Features.**   Our analysis of the conceptual features aims to measure

322   whether the extent to which language input centers around the *"here and now"*:

323   objects/events that are currently present/occurring vs. displaced objects/events. Prior work

324   has quantified such *here-and-now*ness by counting object presence co-occurring with a

325   related noun label [CITE]. The audio format of our data and the coding scheme we use make

326   it difficult to ascertain object presence, so instead of object displacement, in this analysis, we

327   approximate *here-and-now*ness using lexical and syntactic properties of the input. We do

328   this by comparing 1) What proportion of words are temporally displaced?; 2) To what extent

329   can children physically engage in / interact with words' referents?; and 3) What proportion

330   of words have referents that can only be experienced through vision?

331   The last conceptual feature we examined is the displacement of events discussed in

children's linguistic environment, via properties of the verbs in their input. Notably, we are attempting to highlight semantic features of the language environment; however, given the constraints of large-scale textual analysis, we are categorizing utterances based on a combination of closely related syntactic and morphological features of verbs, since these contain time-relevant information. We recognize that these linguistic features do not perfectly align with the temporal structure of the world. We assigned each utterance a **temporality** value: utterances tagged *displaced* describe events that take place in the past, future, or irrealis space, while utterances tagged *present* describe current, ongoing events. A small amount of utterances (n = XXX r n_uncat) were left *uncategorized* because they were fragments or because the automated parser failed to tag any of the relevant features. To do this, we used the udpipe package [CITE] to tag the transcriptions with parts of speech and other lexical features, such as tense, number agreement, or case inflection. To be marked as present, a verb either had to be marked with both present tense and indicative mood, or appear in the gerund form with no marked tense (e.g. *you talking to Papa?*). Features that could mark an utterance as displaced included past tense, presence of a modal, presence of *if*, or presence of *gonna/going to*, *have to*, *wanna/want to*, or *gotta/got to*, since these typically indicate belief states and desires, rather than real-time events. In the case of utterances with multiple verbs, we selected the features from the first verb or auxiliary, as a proxy for hierarchical dominance.

We compare the proportion of temporally displaced verbs using a Wilcoxon rank-sum test, given that a Shapiro-Wilks test indicates that the proportion of displaced verbs does not follow a normal distribution (W = 0.98, p = .977). We find that blind children hear proportionally more displaced verbs than blind children (W = 36.50, p = .003).

Next, we measure whether Child-Body-Object Interaction (CBOI) rating (**muraki2022?**). These norms were generated by asking parents of six-year-olds to rate the extent to which children physically interact with words' referents, from 1 (*things that a*

typical child does not easily physically interact with) to 7 (*things a typical child would easily physically interact with*). We first use the udpipe part-of-speech tags to filter to content words (adjectives, adverbs, nouns, and verbs). Words without a CBOI rating (N = XXX/XXX) were removed. We then compared the distribution of CBOI ratings in word tokens in blind children's input to that in sighted children's input using a two-sample Kilgomorov-Smirnov test. We find that these distributions significantly differ (D = 0.98, *p* < .001) this difference survives Bonferroni correction. Descriptively, low CBOI words were more common in language input to blind children, and high CBOI words were more common in language input to sighted children.
Lastly, we measure whether the language input to blind children contains a different proportion of words referring to visual objects/actions/properties. This is perhaps the dimension that people tend to have the strongest a priori hyptheses about: *Perhaps parents speak less about visual concepts to blind children because they're less relevant to the children's experiences* or alternatively *Perhaps parents speak* more* *about visual concepts, in order to compensate for experiences they perceive their children as missing.* We categorize the perceptual modalities of words' referents using the Lancaster Sensorimotor Norms, ratings from typically-sighted adults about the extent to which a word evokes a visual/tactile/auditory/etc. experience (**lynott2019?**). Words with higher ratings in a given modality are more strongly associated with perceptual experience in that modality. A word's dominant perceptual modality is the modality which received the highest mean rating. We tweak this categorization in two ways: words which received low ratings (< 3.5) across all modalities were re-categorized as *amodal*, and words whose ratings were distributed across modalities were re-categorized as *multimodal*. Using this system, each of the content words in children's input (adjectives, adverbs, nouns, and verbs) were categorized into their primary perceptual modality. For each child, we extracted the proportion of "visual" words in their language environment; this variable was normally distributed (W = 0.96, *p* = .962). We found no differences across groups in the proportion of highly visual words (*t*(25.11) =
0.32, $p = .755$).
387 **Patterns in Language Input.**

Blind (N=15)

388

Sighted (N=15

Lastly, we also ran an exploratory analysis testing for patterns among these measures of language input. First, we re-aggregated the language input variables such that each child had a single value for each predictor; this required calculating MLU over child rather than over speaker and giving each child's input a mean child-body-object interaction rating. Next, we generated correlation matrices separately for the blind sample and the sighted sample, using Kendall's Tau correlations; see Figure **??**. We then compared correlations among variables across groups. To reiterate, this analysis is purely exploratory and descriptive in nature.

Looking across matrices, we found similarities in how properties of children's language input patterned across groups. To highlight one of the strongest common relationships, in both samples, children who heard more adult words were involved in more conversational turns ($r_{\text{blind}} = 0.60$, $p_{\text{blind}} = .002$; $r_{\text{sighted}} = 0.65$, $p_{\text{sighted}} = .001$) and had lower type-token ratios ($r_{\text{blind}} = -0.69$, $p_{\text{blind}} < .001$; $r_{\text{sighted}} = 0.47$, $p_{\text{sighted}} = .019$). However, we also found some differences, where associations ran in the *opposite* direction: For blind kids but not sighted kids, higher BOI ratings was associated with a greater proportion of temporally displaced verbs; for sighted kids, higher BOI was associated with *less* temporal displacement ($r_{\text{blind}} = 0.41$, $p_{\text{blind}} = .047$; $r_{\text{sighted}} = -0.41$, $p_{\text{sighted}} = .047$). For blind kids only, proportion of child-directed speech was associated with *lower* proportion of highly visual words ($r_{\text{blind}} = -0.30$, $p_{\text{blind}} = .157$; $r_{\text{sighted}} = 0.16$, $p_{\text{sighted}} = .451$).

Discussion - ignore me for now

This study measured language input to young blind children and their sighted peers, using the LENA audio recorder to capture naturalistic speech in the home. We found that across many dimensions of language input, parents largely talk similarly to blind and sighted children, with a few nuanced differences, that we discuss further below.

Quantity

Across both of measures of language input quantity, one estimated from the full sixteen hour recording (Adult Word Count) and one precisely measured from a 40-minute window of that day (Manual Word Count), blind and sighted children were exposed to similar amounts of speech in the home. Quantity was highly variable *within* groups, but we found no evidence for *between* group differences in input quantity.

Interactiveness

We quantified interactiveness in two ways: through the LENA-estimated conversational turn count, and through the proportion of child-directed speech in our manual annotations.

Again, we found no differences across groups in the amount of parent-child interaction. This finding runs counter to previous research; other studies report *less* interaction in dyads where the child is blind (Rowland, 1984; **perez-pereira2001?**; Grumi et al., 2021; Kekelis & Andersen, 1984;, Moore & McConachie, 1994; Gunilla M. Preisler, 1991; **anderson1993?**). Using a non-visual sampling method (i.e., our audio recordings) might provide a different, more naturalistic perspective on parent-child interactions, particularly in this population. For one thing, many of these studies (e.g., Kekelis & Andersen, 1984; Moore & McConachie, 1994; Gunilla M. Preisler, 1991; **perez-pereira2001?**) involve video recordings in the child's home, with the researcher present. Like other young children, blind children distinguish between familiar individuals and strangers, and react with trepidation to the presence of a stranger (McRae, 2002; **fraiberg1975?**); for blind children, this reaction may involve "quieting", wherein children cease speaking or vocalizing when they hear a new voice in the home (McRae, 2002; **fraiberg1975?**). By having a researcher present during the recordings[1] , prior research may have artificially suppressed blind children's initiation of interactions. Even naturalistic observer-free video-recordings appear to inflate aspects of parental input, relative to daylong recordings (Bergelson, Amatuni, Dailey, Koorathota, & Tor, 2019). In these cases, the video camera acts as an observer itself, making participants aware of its presence, limiting participants' mobility, and therefore shrinking the pragmatic scope of possible interactions. Together, these factors could explain why past parent-child interaction research finds that blind children initiate less (Dote-Kwan, 1995; Moore & McConachie, 1994; **anderson1993?**; **kekelis1981?**; **troster1992?**), that parents do most of the talking (Kekelis & Andersen, 1984; **anderson1993?**), and that there is overall less interaction (Rowland, 1984; **nagayoshi2017?**; **rogers1984?**; **troster1992?**).

Additionally, a common focus in earlier interaction literature is to measure visual cues

---

[1] Fraiberg (1975) writes "these fear and avoidance behaviors appear even though the observer, a twice-monthly visitor, is not, strictly speaking, a stranger." (pg. 323).

of interaction, such as shared gaze or attentiveness to facial expressions (Baird, Mayfield, &
Baker, 1997; Gunilla M. Preisler, 1991; **rogers1984?**). We can't help but wonder: are visual
markers of social interaction the right yardstick to measure blind children against? In line
with MacLeod and Demers (2023), perhaps the field should move away from sighted
indicators of interaction "quality", and instead try to understand try to situate blind
children's interactions within their own developmental niche, one that may be better
captured with auditory- or tactile-focused coding schemes.

Linguistic Features

Along the linguistic dimension, we measured type-token ratio and mean length of
utterance. Type-token ratio was similar across groups, and in line with type-token ratio in
other child-centered corpora (e.g., **newman2015?**). However, we found slightly but
significantly higher MLU in blind children's language environment. The MLU finding runs
counter to common advice: Parents of children with disabilities (including parents of blind
children! e.g., FamilyConnect (n.d.); (**chernyak?**)) are often advised to use shorter, simpler
sentences with their children, in order to promote children's understanding. We find instead
that the language environments of blind children contain *longer* utterances, which could
suggest that consciously modifying your linguistic behavior is difficult for parents. In any
case, this advice is not supported by the literature: evidence suggests that longer, more
complex utterances are associated with better child language outcomes in both
typically-developing children (Hoff & Naigles, 2002 Mar-Apr) and children with cognitive
differences (**sandbank2015?**).

Conceptual Features

The conceptual features of language input feel slipperiest to operationalize. For this
analysis, we chose to capture *here-and-now*-ness by measuring the proportion of temporally
displaced verbs, the distribution of high vs. low child-body-object interaction ratings for
content words, and the proportion of highly visual words. Relative to other aspects of

language input, the conceptual dimension seemed to vary most across groups: though blind and sighted participants were exposed to a similar proportion of highly visual words, blind children heard more displaced verbs and their content words were distributed slightly more to the not-interactable side of the child-body-object interaction ratings.

Furthermore, our exploratory analysis points to potential group differences in the *context* of conceptual information. Blind children's proportion of temporally displaced verbs was inversely correlated with their mean child-body-object interaction rating, whereas sighted children showed the reverse relationship. Could this suggest that when sighted children hear about words that are perceivable or manipulable, it tends to be in the context of co-present objects / events, but when blind children hear about things that can be interacted with, it tends to be related to past/future events? Additionally, while we found that overall, blind and sighted children hear a similar proportion of highly visual words (blue, mirror, rainbow, see), blind children (but not sighted children) who receive *more* child-directed speech seem to receive *less* of this highly visual language. Our present analyses can only hint at potential relationships between these variables at the child level, but as more dense annotation becomes available, we can explore the social and environmental context of conceptual information as it unfolds across discourse.

Patterns in Language Input

Before synthesizing any of these differences, we wish to highlight again how much variability there is *within* groups and how much consistency there is *between* groups. One could imagine a world in which the language environments of blind and sighted children are radically different from each other. Our data do not support that hypothesis. Rather, we find far more similarity across groups than difference, and all differences were small in magnitude. This is worth emphasizing and re-emphasizing: across developmental contexts, including, as we show here, visual experience, children's language input is resoundingly similar (Bergelson et al., 2022).

⁴⁹⁸   When we zoom into more fine-grained aspects of the input, we found that blind

⁴⁹⁹ children's language environments contained longer utterances, more temporal displacement,

⁵⁰⁰ and content words that are harder for children to interact with. Together, these features

⁵⁰¹ seem to suggest that blind children's input is more similar to adult-directed speech [cite cite

⁵⁰² cite] than sighted children's. This does not seem attributable to differences in addressee: our

⁵⁰³ annotators indicate that there is a similar proportion of child-.vs.adult-directed speech across

⁵⁰⁴ the two groups.

⁵⁰⁵   The small differences in linguistic input might also be accentuated by differences in

⁵⁰⁶ nonverbal communication between blind infants and their sighted caregivers. Young children

⁵⁰⁷ born with visual impairment may differ in their nonverbal communication cues. For example,

⁵⁰⁸ (G. M. Preisler, 1995) found that 6–9-month-old blind infants communicated using leaning,

⁵⁰⁹ eyebrow raising, and lip movements. Caregivers who responded to these nonverbal cues as

⁵¹⁰ conversational turns had higher rates of interaction with the child, higher rates of

⁵¹¹ appropriate response, and increased positive affect. By contrast, caregivers who did not

⁵¹² recognize these signals as communicative had lower rates of response and increased negative

⁵¹³ affect. also Baird et al. (1997) (N=7, parents interpret behaviors differently)
